Preface

The purpose of this study was to develop a technique for Mode II fracture testing of small composite specimens. The technique could be varied for uses with other fracture modes and for high temperature applications.

At this opportunity, I would like to express my gratitude to my thesis advisor, Dr. S. Mall for his advice and guidance.

I would like to extend a special thanks to Dr. T. Nicholas, of AFWAL/MLLN, and his staff of engineers. Larry P. Zawada provided extensive help with composite fabrication and post mortem analysis. Stephan Russ provided guidance on specimen preparation. Jay R. Jira's help was instrumental in getting the laser interferometry up and working.

I deeply thank my wife, Diane, for the typing, encouragement, patience and understanding she showed during the time of this study.

Abstract

The need for an accurate fracture toughness testing technique for fiber reinforced ceramic composites was identified. A technique was developed to measure small crack mouth displacements over small gauge lengths of small glass-ceramic composite specimens during loading. The technique was applied to Mode II crack propagation. A loading fixture capable of exerting and measuring small loads was developed. A technique to measure compliances in small composite specimens was perfected. The validity of using a laser based interferometric technique to determine the instant of crack initiation was studied. Finally, the Mode II critical strain energy release rate of interlaminar delamination growth was evaluated. Sample results for a 1723 glass matrix, silicon carbide fiber composite are included and recommendations for further study are described. (The ses).

I. INTRODUCTION

Problem

As new technologies push material usage closer to their physical limits, fracture mechanics has become an important tool in the design process. The durability of a part or structure is often directly related to a material's resistance to crack initiation and growth. By accurately predicting stable crack growth behavior, the usable life of a component can be assessed quantitatively. This aids the engineer in both his design selection and maintenance scheduling.

Griffith (1,2) provided the basic concepts of fracture mechanics in the 1920's and Irwin (3) and others followed on his work in the 1940's and 1950's. The early work was done with homogeneous isotropic materials, first with glass and then with metals (4). In recent years, composites have received an increasing amount of attention. Any analysis of composites is difficult due to their non-homogeneous and anisotropic nature (5).

With the high temperature requirement for new engines, new materials are needed. Researchers have sought to develop tough ceramics whose performance characteristics retain the best properties of their parent ceramics and have the additional quality of not being susceptible to fracture (6-9). The development of fiber

reinforced glass-ceramic matrix composites is one of the best examples in this direction.

Since the motivation for developing these ceramic composites is to utilize their high toughness in structural applications, an accurate fracture toughness measurement technique is needed. There is a standard procedure recommended by the American Society for Testing and Materials (ASTM) for finding the fracture toughness for metals at room temperature (10). No such procedure exists for fiber reinforced ceramic composites.

According to Jenkins (11), "Fracture testing of structural ceramics is complicated by the lack of an accurate technique for measuring the small crack opening displacement. This is further complicated by the small crack sizes which are associated with specimens at failure". Further, the composite specimens available for testing are small due to the limited availability of material. In addition, fracture testing at very high temperatures is required since these ceramic composites are being developed for high temperature applications.

Kobayashi and Jenkins were able to determine specimen compliance and fracture toughness parameters using a laser interferometric strain gauge (11,12). The laser interferometric strain gage (LISG) measures small displacements of the order of microns over small gauge lengths. Sharpe (13-16) was one of the pioneers in using

this technique for measuring crack surface displacements. In the past, this technique was primarily used with metallic specimens that had good reflecting surfaces. Due to the low reflectivity of most ceramic and glass composites, this technique has not been commonly used for these materials. To get around this problem, metal tabs have been glued onto the composites and the indents were placed on the tabs (12). The majority of this work has been applied to Mode I crack opening.

With composites, fracture due to crack growth in shear sliding Mode II or Mixed Mode I and II is of a potentially greater significance. This is particularly true with unidirectional fiber reinforced composites. The composite fibers serve as obstructions to Mode I fractures perpendicular to the fiber direction. However, cracks oriented parallel to the fibers can propagate and fail catastrophically in Mode II. To model the Mode II fracture, a three point bend configuration is used. The end-notch flexure (ENF) specimen has been successfully used to measure G_{IIC} , the critical strain energy release rate of interlaminar delamination growth in composites (17).

The flexure specimen is a beam with a crack located on the neutral plane at one end. The beam is subjected to three-point bending. Mall (18), used this type of beam when he investigated Mode II failure of composites using a finite element technique. Giare (19) measured Mode II

fracture toughness using a clip gauge to measure relative displacement of a crack surface on an end-notch flexure specimen. He was able to apply Linear Elastic Fracture Mechanics (LEFM) to a unidirectional glass fiber reinforced composite material in Mode II. A good technique is still needed that can accurately predict Mode II fracture at a wide range of operating temperatures.

Objective

The objective of this study was to develop a technique to measure small crack mouth displacements over a small gauge length of a small glass-ceramic composite specimen during loading. The technique was specifically applied to Mode II crack propagation. The utility of this technique was demonstrated for room temperature fracture testing of ceramic composites. A variation of the technique could also be used effectively at elevated temperatures in the future.

Approach

The experimental program involved several aspects. First, a loading fixture capable of exerting and measuring small loads was developed. Measurement of the load point displacements was also incorporated into the apparatus. Next, a technique to measure compliance in small composite specimens was perfected. Then a laser based interferometric technique was used to measure crack opening displacement and to determine the instant of crack initiation. Finally, the Mode II fracture of a

unidirectional glass matrix composite was investigated using the technique and hardware that was developed by using the end-notch flexure specimen.

The composite used was a 1723 Corning glass matrix with silicon carbon yarn as reinforcing fibers. This ceramic composite is currently being developed and studied by engineers at the Air Force Materials Laboratories. The results of this study provide an accurate experimental tool to perform fracture toughness testing of many structural composites in a variety of conditions.

II. BACKGROUND

Griffith developed one of the basic theories of fracture mechanics in the early 1920's (1,2). Griffith used brittle glasses to derive equations for crack propagation. His equations were based on the idea of critical energy release rate. He stated that "crack propagation will occur if the energy released upon the crack growth is sufficient to provide all the energy that is required for crack growth (4)".

The field of fracture mechanics took on greater importance in the 1940's and 1950's with the increased use of high strength materials. Irwin (3) applied fracture mechanics to metals. He did extensive studies on the effects of stress on the crack tip and the crack tip plastic zone size. Broek (4) presents a good history of the basic problems and concepts of Linear Elastic Fracture Mechanics in his book. The bulk of these works, however, deal with homogeneous isotropic materials such as metals and simple glasses.

Composites are non-homogeneous and anisotropic in nature. This complicates any analysis of composite materials. The basic mechanics of composite materials are described by Jones (5). Many of the new composites are being developed for high temperature applications in today's engines.

One of the areas of study for these applications is tough ceramic composites. The toughening mechanisms for ceramic composites were described by Jelinek (20). Jelinek lists three methods of toughening ceramic composites: 1) increase the local driving force necessary to propagate cracks to failure, 2) locally increase the mechanical energy consumed per unit area of propagation of any crack, or 3) decrease the local strain by cracking, which reduces the stress concentration. Jelinek also lists six ceramic matrix composite toughening concepts.

The Ceramic Bulletin (21), provided information on processing techniques for fiber-reinforced ceramic matrix composites. The article deals with properties and processing of several composites, but concentrates mainly on silicon carbide reinforced glasses and composites. The article discusses processing from the initial slurry, through hot pressing and includes information on future needs and directions.

The Naval Research Laboratory has done work on refractory-ceramic fiber composites (22). The engineers at the Research Laboratory present the significant opportunities, problems, and possible solutions associated with ceramic fiber composites. Processing, mechanical properties and limitations of the composites were all discussed.

Hasselman (23-25), did extensive work in ceramic composites. His works concentrated in the areas of thermal shock and thermal stress fracture. He stated that tailoring of material properties could be achieved to improve resistance to fracture initiation and resistance to crack propagation. This was achieved by adding substances to the matrix of a composite.

Kelly (26), used Hasselman's theories to study the influence of the addition of silicon carbide whiskers and zirconia on the material properties of a parent ceramic. Valentine (27), also followed some of Hasselman's techniques in the study of strength and thermal shock behavior of a ceramic composite. Valentine compared results based on varying compositions of a particulate and varying temperatures up to 1500°C. Both Kelly and Valentine characterized the microstructures of the composites that resulted from their experimentation.

One of the acknowledged experts in the area of glass-ceramic matrix composites is Dr. Karl Prew. He has done extensive research at the United Technologies Research Center and he has published numerous articles on reinforced glass matrix composites and glass ceramic matrix composites (7-9, 28-36).

Prew has completed a series of reports for the National Aeronautics and Space Administration on Research on Graphite Reinforced Glass Matrix Composites. In these reports Prew describes composite fabrication procedures,

composite characterization procedures, and the results and discussion of those procedures.

Prewo described three point flexural strength, creep and fatigue tests for several glasses, including aluminosilicate glass composites. He found that the glass and glass-ceramic matrix composites to show great promise for high temperature applications. He did not, however, do any Mode II testing with end-notch flexure specimens.

Prewo did a range of tests and property studies at high temperatures up to about 1000°C. He noted, "The predominant mode of failure from room temperature to 600°C is local delamination of the composite along the fiber direction, indicative of a weak bond at the fiber matrix interface" (33).

Additional fabrication information was provided by Mr. Larry Zawada of AFWAL/MLLN (37). Mr. Zawada has been experimentally preparing small samples of the 1723 glass matrix composite. He has also been involved with mechanical property testing of this ceramic composite.

There are several sources which deal with fracture toughness testing. The American Society for Testing and Materials (ASTM), has several sources for metallic materials (10,38). ASTM also published guidelines for flexural tests of plastics and electrical insulating Materials (39).

Kobayashi has detailed experimental techniques in fracture mechanics (40, 41). He describes compliance measurements, testing systems and instrumentation, mixed-mode stress intensity factors, laser interferometry and many other fracture mechanics testing techniques.

Kobayashi also served as an advisor to a doctoral student, M.G. Jenkins. The two collaborated on several articles and a dissertation on short crack growth of ceramic composites (11,12,42,43). Jenkins and Kobayashi performed Mode I tensile testing on a number of metals and ceramics. The result of their study was the development of a technique for fracture toughness testing of ceramics. Jenkins used a laser interferometric strain gauge to measure crack mouth opening displacements at high temperatures. He perfected a technique of indenting small metal tabs that were affixed to the ceramic specimens. He was able to measure compliance, work of fracture, and crack mouth opening displacement. The compliance was used to calculate an effective crack length and the crack growth resistance. This led to determinations of the stress intensity factor K_I , and the strain energy release rate G_I .

The laser interferometric strain gauge was extensively tested by Sharpe (13-16, 44-48). For the past twenty years Sharpe has used laser interferometry for various applications of displacement measurement. He has used a metal tabbing technique for room temperature

testing of graphite-epoxy components. He did preliminary work on the applicability of the measurement of displacements parallel to a crack in a composite specimen. Sharpe found that the LISG measurements parallel to the crack were crude and only approximate. Sharpe also did high temperature work on displacements over short-gauge lengths. The majority of Sharpe's testing concerned fatigue crack growth.

Locally, Bar-Tikva used laser interferometry in his thesis work on an experimental weight function method for stress intensity factor calibration (49). Bar-Tikva used the LISG to find stress intensity factors of four-point bend specimens. A computer program was then used to construct a weight function. Bar-Tikva (50), combined with Grandt and Palazotto in a presentation of the results and conclusions that were drawn from the previous work on the weight function.

Mr. Jay Jira, an engineer of the Metals and Ceramics Division, AFWAL/MLLN, completed a computer program to record and process the fringe input from the laser interferometric strain gauge (51). His work is on-going in this field in the area of fatigue crack growth in metals. Jira's program was originally intended for Mode I fracture.

The majority of the laser interferometric work has been with isotropic materials. It has been proven very reliable for measuring small displacements in these

materials. The use of the LISG with composites, especially in Mode II fracture, is fairly new.

According to Jones (5), the effect of a transverse shear may be more important for laminated composites than for isotropic materials. This view is strongly supported by Giare (19). Giare studied Mode II failure of reinforced composites. He used clip gauges to measure the crack mouth opening displacements versus load. These measurements led to the measurement of critical Mode II stress intensity factor. Giare showed that the crack growth resistance curve is a material property and that linear elastic fracture mechanics applies well to unidirectional glass fiber reinforced composite materials in Mode II fracture.

Mall (18), applied a finite element analysis to an end-notch flexure specimen in Mode II. He investigated the effects of overhang on the Mode II strain energy release rate.

Finally, once all the testing has been completed the fractures must be examined and understood. Wiederhom (52) investigated brittle fracture in ceramics. He stated that the fracture behavior of metals and ceramics were different. Fracture in ceramics was controlled by the microstructure on the crack tip. Lankford (53) completed a report on damage mechanisms in ceramic composites. Lankford tested glass-ceramic matrix composites reinforced with silicon carbide fiber. He tested unidirectional and multiaxial reinforced composites in compression. His

damage characterization goes to the microscopic level.

Marshall (54) studied failures during both tensile and flexural loading.

III. EXPERIMENTAL PROCEDURE

The experimental procedure involved fracture testing of straight-notched, pre-cracked, end-notch flexure specimens of unidirectional fiber reinforced beams at room temperature. The beam was composed of 1723 Corning glass matrix (see Table I) with a silicon carbide yarn fiber (see Table II). Appendix A describes composite fabrication and shows a photograph of the ceramic composite's fiber and matrix. A linear variable displacement transducer (LVDT) and loadcell were used to monitor the load vs. load point displacement during load application and subsequent fracture. The resulting load vs. displacement curves were used to calculate compliance vs. crack length curves. The laser interferometric strain gauge was used to monitor crack opening displacement. The values of displacement vs. load were used to determine the critical load accurately. The specimen geometries, pre-cracking, loading apparatus, compliance technique, laser interferometric strain gauge, reflective tabs and output are discussed separately in the following sections.

Specimen Preparation

An end-notch flexure specimen was used in this study. The overall dimensions of the beam were 2.0 x 0.30 x 0.20 inches, with a notch width of approximately 0.010 to 0.015 inches, and a testing span of 1.50 inches. The dimensions of each specimen were measured with a micrometer and were

all within two percent of the stated values. Figure 1 defines the dimensions for the specimen. The machined notch length varied from 0.1 to 0.2 inches and was followed by various lengths of precracking. The beam thickness corresponded to a forty ply lay-up of the glass composite. The material fabrication is explained in appendix A. The beam width was chosen from previous experiences with this composite by engineers in the Air Force Materials Laboratory.

Figure 1. Specimen Dimensions

The notches were cut using a liquid cooled diamond wheel saw. The resulting notch widths were 0.010 to 0.015 inches. The notches were cut at the edge of the beam at half of the height. This would correspond to the location

of the beam's neutral plane. The fibers run parallel to this plane and notch.

Pre-cracking

In order to create the natural crack front for accurate fracture toughness measurement, the machined notch was extended by precracking it before conducting actual tests. A white paint was applied on one side of the specimen from the notch to the back edge. The white paint allowed for easier monitoring of crack growth on the black fibrous composite. A straight razor was used to cut a sharp crack in the center of the blunt notch tip. After the desired crack length was decided and the location marked with a thin pencil, a transverse load was applied at this point. The compressive load was applied by using a small one inch metal C-clamp. To ensure that the transverse load was applied at the desired point, two one-quarter inch wide strips of metal were precisely positioned between the sides of ceramic specimen and the C-clamp (see Figure 2). The strips ran from the rear of the specimen to the point where the crack was intended to arrest. The strips were used to more evenly distribute the load from the C-clamp and to create a track for the possible movement of the load location. For all practical purposes, the pre-crack was arrested at the desired point.

Figure 2. Pre-crack Configuration

The C-clamp holding the specimen was then mounted in a vise, which was attached to a workbench. A travelling microscope was positioned to view the crack tip. For best results, the specimen face should be parallel to the travel of the ten power microscope. In this way, it is easy to follow the crack as it propagates to the desired point.

A small screwdriver was then inserted in the notch and gently tapped with a hammer. This wedge action caused the crack to slowly propagate until it reached the area of the applied load. By watching the crack growth in a microscope the exact point of the crack tip could be determined and marked with a thin pencil. The overall crack length

was then measured and recorded for each specimen. These were also verified later on by the post-mortem examination of the fractured surfaces after conducting the fracture toughness test. This is described in the results section to follow.

Loading Apparatus

A custom-made loading apparatus was fabricated for the present study. It consisted of a rigid steel frame enclosing a moving platform. The platform is manually raised and lowered by a screwjack mounted to the bottom of the frame (see Figures 3. & 4.).

Figure 3. Three-Point Bend Platform

Figure 4. Loading Apparatus

The platform uses bearing sleeves and guide rods to stabilize vertical travel. Attached to the moving platform is a three-point bend configuration with the two lower rollers set 1.5 inches apart. The top roller is glued to a threaded stud attached to a load cell. The load cell is an Interface Model SM-1000 with a range of 1000 lbs. The load is applied by raising the stage to the load cell using a manually operated screwjack. The stage displacement and load point displacement are monitored by a LVDT. The LVDT is a Robinson-Halpern Model 225A-125 which has a range of

± 0.125 inches and an output of up to 2.19 volts at maximum range.

The outputs from the LVDT and load cell are fed to a two-channel Hewlett Packard X-Y Plotter. The resulting plots of load vs. load point displacement can be used to find the specimen compliance. The LVDT was calibrated to an accuracy of a thousandth of an inch and the load cell was calibrated to a pound.

Compliance Measurement

Based on preliminary testing on some thin composite specimens that were made previously, the approximate critical load was established for the tested specimen configuration. By staying well below that load, the load vs. displacement curves showed a linear relationship. Using the equation:

$$C = v/P \quad (1)$$

where

C = compliance

v = load point displacement

P = applied load

The compliance was calculated for different crack lengths from several identical specimens. Effective crack lengths were varied by testing specimens of varying initial crack

lengths by moving the specimens on the bottom rollers (see Figure 3.). According to Mall (18), the overhang portion of a beam has no effect on the evaluation of G_{II} . This technique allowed the testing of several effective crack lengths on each specimen. To ensure minimum errors in experimentation, each crack length was tested three times and the compliance value was then averaged over the three. Finally, to minimize the friction forces and closure between crack faces, 0.012 inch metal rollers were inserted in the notches during this measurement process. Mall (18) suggested this technique to negate the undesirable effects of friction in the region above the support pin.

Each beam was inserted on the three point bend platform and carefully placed perpendicular to the upper loading pin. The specimen was then moved parallel to a fine graduated metal rule attached to the platform. The overhang portion of the beam was then measured. The overhang portion is the length of beam from the point above the lower support pin to the end of the specimen. Mall (18) proved that only the area between the two lower support pins effect the evaluation of G_{IIC} . The amount of overhang was then subtracted from the actual crack length to provide an accurate measurement of effective crack length.

The three-point bend platform was then raised until the specimen was just below the upper loading pin but still not touching. The Y-axis was set to zero on the X-Y plotter. This gave the reference value for zero load.

Returning to the loading apparatus, the platform was then raised until it touched the loading pin and a small load was applied. The output of the LVDT was then checked with a multimeter to insure that the readings were in the linear range of the LVDT. If the readings were outside the linear range, the LVDT was adjusted accordingly. Once the LVDT was properly aligned, the X-axis (the displacement axis) of the X-Y Plotter was set to zero and the pen was set to record.

The load was then applied until a previously determined displacement was achieved. The displacement corresponded to an approximate load that was well below the expected critical load. At the end of loading the pen was raised on the plotter and then the specimen was unloaded. This cycle was completed three times before the specimen was moved slightly and another effective crack length was tested.

Finally, several specimens were run at various effective crack lengths. This provided load vs. load point displacement readings for effective crack lengths from zero to half span of the beam. This also gave overlapping values of readings from the different specimens. The compliance was then calculated using the equation $C = v/P$.

After all the compliance curves were generated, a crack length was chosen and the specimen was loaded until shear failure occurred. The crack propagated towards the center of the loading span. This process was recorded on the X-Y plotter in the same manner as the compliance measurements. It was during this phase that the laser interferometric strain gauge was required to determine the actual measurement of critical load at crack initiation.

Laser Interferometric Strain Gauge

The Laser Interferometric Strain Gauge (LISG) was used by Sharpe (15) to measure displacements of less than a micron. The LISG measures the relative displacement of two small reference marks. The reference marks are made by using a diamond micro-hardness indenter. The indenter makes square based pyramids whose size is based on the load used on the indenter and the material being indented. Sizes of indents range from 20 microns to over 100 microns. Spacings between indents range from 50 microns to 800 microns based on the application (Ref. 15, 19, 20).

A laser acts as a coherent light source to illuminate the indentations. The beam is reflected at an angle α off the indentation faces. The reflected light from the two closely placed indentations overlaps and forms a interference fringe pattern on both sides of the incident laser beam.

The application of load causes the specimen to deform and the indents to move relative to each other. The motion of the indent spacing and the fringe order is related by the equation:

$$\delta d = \delta m \lambda / \sin \alpha \quad (2)$$

where

δd = change in distance between indentations

λ = wave length of the light source

δm = change in fringe order

α = laser incidence angle

The wavelength of the helium-neon laser is 0.633 microns. The laser incidence angle is approximately 44 degrees, which is related to the geometry of the indentations. The indent spacing was 300 microns prior to loading.

Photo detectors are placed at fixed points to monitor the fringe patterns and count the number of fringes passing. By using a photo detector on each side of the incident beam, the rigid body motion can be eliminated. This is done by averaging the left and right fringe number.

Since the glass composite in this study was not very reflective, tabs are required for employing the laser interferometric technique.

Reflective Tabs

Two thin metallic tabs were attached to each specimen. The tabs were laid across the pre-crack and epoxied at two corners, diagonally across from each other (see Figure 5). The two independent tabs were then indented. The method of epoxying the tabs caused one tab to move with the upper shear surface and the other tab to move with the lower shear surface. The indents moved away from each other horizontally. The movement of these reflective indents was the quantity measured using the LISG.

Figure 5. Tabbing Method

The reflective tabs were cut from a 0.004 inch thick sheet of aluminum. Aluminum is highly reflective and is also pliable enough to provide good indents and ease of preparation at room temperature. At higher temperatures, platinum tabs have been used (12).

Using a razor, a rectangular piece of aluminum, approximately 0.2 x 0.1 inches was cut from the sheet. The top of the rectangular piece was then marked. Using a hammer blow to a straight razor, this piece was cut in two halves parallel to the long side. Figure 5 shows the two tabs schematically, while Figure 6 shows a photograph of the highlighted area.

Figure 6. Reflective Tabs

Magnified X25

A 2.0 x 0.1 inch piece of cellophane tape was placed on the shiny side of one of the tabs. The tape was rolled back and epoxy was applied to the bottom of the tab. After the tape was aligned, the tab was carefully placed near the crack tip and the epoxy was pressed away from the crack. The tape applied the needed pressure and the epoxy was left to cure for two hours. The tape was then removed. The second tab was carefully positioned on the composite next to the first tab. The lower portions of the two tabs were taped to the specimen. The exposed end of the first tab was slightly curled up to separate it from the second tab. The exposed end of the second tab was then carefully epoxied. The second tab was taped to the specimen and left to cure for two hours. After the epoxy had cured, all the cellophane tape was removed. The tabs were then ready to indent.

The two indents were generated using a 300 gram load on a Wilson hardness tester and a pyramid shaped diamond microhardness indenter. The resulting indents were approximately 130 microns on a side and were spaced approximately 300 microns apart using a precision stage and microscope (see Figure 7).

Figure 7. Reflective Tabs and Indents
Magnified 200X

The resulting indent planes were angled at approximately 45 degrees to the incident laser beam when the specimen was perpendicular to the loading pin. The two indents were illuminated by a coherent laser beam from a 10 milliwatt Helium-Neon laser (see Figures 8 and 9). The two over-lapping reflections produced interference fringe patterns at four locations located at 45 degrees relative to the beam. Only the two reflections at the sides are important for horizontal motion.

Figure 8. Schematic LISG Arrangement

Figure 9. Actual LISG Arrangement

The fringe patterns (see Figure 10), were reflected onto two photomultiplier tubes located 22 inches from the specimen. The active face of the photomultipliers was covered by a narrow slit 5 millimeters high, smaller than 1 fringe in size. The slit allowed distinction between individual fringes. The use of two photomultipliers negated rigid body motion by using an average value of displacement between the two readers. An isolation table provide adequate isolation from random vibrations of the surroundings.

Figure 10. Fringe Pattern Reflections

Using equation (2), the displacement between the two indents near the crack surfaces was found as a function of applied load. This allowed for determination of the critical load. The fringe information and load were input to a Tektronix 4052 computer system through A/D converters. The fringe information was used to determine the relative displacement between the locations of the two indents. The displacement was looked at in a qualitative manner to determine the instant that the two crack facet moved in shear. During the shearing process the relative displacements changed abruptly from a stable linear load-displacement relationship to a non-linear relationship. The load at the point of change was identified as the critical load.

RESULTS AND DISCUSSION

Compliance

Seven of the end-notched flexure specimens were tested to generate a crack-compliance relationship which is required for G_{IIC} as discussed later. Each specimen was tested at several effective crack lengths by moving it horizontally across the two lower roller supports. It was very important to test each specimen as many times as possible due to the limited availability of materials. This technique provided multiple compliance readings for crack lengths ranging from 0.0 inches to midspan at 0.75 inches. The compliance was found using equation (1).

Since the specimen height varied slightly among the specimens (see Table III), the compliances were normalized by the cube of the height. The normalized compliances are plotted as a function of crack length in Figure 11. The results show the expected trend of the compliance increasing with crack length. Using the regression analysis, a curve was fitted to the experimental data. This is shown as a solid line in Figure 11 and is given as follows:

$$C = 1.646656 * \exp(0.506834)a/W \quad (3)$$

where

a = the crack length from the support pin

$W = L$, the width of a half span

Figure 11. Experimental and Analytical
Compliance Curves

T-21	1.984	.305	.203	.75
T-24	1.953	.303	.199	.75

As mentioned previously, the end-notched flexure specimen has been employed extensively to measure Mode II interlaminar fracture toughness, G_{IIC} in composites. A theoretical compliance relation has been developed by Russell (17) which is given below:

$$C = \frac{1 + 1.5(a/L)^3}{4E_{11}b(h/L)^3} \quad (4)$$

This analytical relation was developed based on the simple linear beam theory. The present measured compliances were compared with the theoretical relation given in equation (4). This is also shown in Figure 11.

All variables in the theoretical compliance expression are known except for E_{11} . Young's Modulus, E_{11} , was calculated from equation (4) by using the experimental compliance for a crack length of zero. The calculated value of Young's Modulus was found to be 9.257×10^6 pounds per square inch.

The experimental and theoretical compliance relations are in reasonable agreement with each other up to $a/W = .70$, but they quickly diverged after that. This difference can be attributed to several factors, for example, the small size of the specimen or the simple beam theory. The nature of the small size of the fibrous composite provided much higher compliances at midspan in the analytical representation than in the experimentation. A more appropriate analytical model needs to be found for use with the small composite specimens.

Fracture Toughness

As stated, the objective of this study was to develop a procedure, as well as to measure, the critical strain energy release rate, G_{IIC} , for a fiber reinforced ceramic composite. Several specimens of the 1723 Glass matrix/silicon carbide fiber composite were tested until fracture. A typical load-displacement curve is shown in Figure 12.

All of the load-displacement curves are characterized by an initial section of linearity. The linear portion

extends past two hundred pounds of applied load. This portion of the curve corresponds to the elastic deformation of the beam.

The linear portion of the curve was followed by a nonlinear portion until the load ultimately dropped off as a result of fiber failure. Based on observations during testing, it was thought that the nonlinearity was a result of shear failure along the neutral plane.

The critical load is required to find G_{II} . Although shear fracture was evident during the nonlinear portion of the load-displacement plot, it was not possible to visually observe the instant of fracture initiation. Since visual observation could not back up our theory that fracture initiation occurred at the point of nonlinearity, the laser interferometric strain gauge was employed.

The laser was aligned so that the reflections from the two indents formed strong fringe patterns at angles of 45 degrees to the specimen surface. The photomultiplier tubes were then positioned in the center of each fringe pattern.

During loading, information from the photomultiplier tubes and the load cell was input to the computer once every second. The voltage from the photomultipliers showed steadily increasing or decreasing strength. By noting the local high and low points, the relative displacement was measured to half a fringe.

Figure 12. Loading to Fracture

During the loading process, the specimen provided a strong fringe pattern until a point when the patterns suddenly visibly degraded (see Figure 13). The loading process was continued and the LISG still recorded fringe information. The fringe intensity, however, had faded. The rate of fringe movement also increased rapidly at the point.

Figure 13. Fringe Readings

The sudden degrading of the fringe pattern was believed to be the point of rapid shear failure. The data from the LISG was plotted and the average fringe motion was converted to a relative displacement (see Figure 14).

Figure 14 shows the displacement between the fracture surfaces of the beam. Like our previous load displacement curve, there is initially a linear relationship between load and displacement. At a load of 225 pounds the relationship becomes nonlinear. At this point, the rate of displacement between indents increased greatly. This trend is consistent with the rapid shear failure of a brittle material.

The load of 225 pounds was only three pounds lower than the point of nonlinearity on the load-load point displacement curve. This backs up our theory on critical load. The point of nonlinearity from all the load-load point displacement curves was then used as the critical load in the calculation of G_{IIC} .

Figure 14. Relative Displacement of Shear Plane

Critical Energy Release Rate

The instant of crack initiation was taken at the point of nonlinearity as described earlier. The values of critical load, that were required for the calculation of the strain energy release rate, were now available. A chart of critical load vs. crack length was prepared (see Figure 15). Finally, an analytical and an experimental value of the strain energy release rate was calculated for each of the fractured specimens. The analytical energy release rate was based on the earlier theoretical compliance expression and the simple beam theory. The analytical equation used was (17):

$$G_{II} = \frac{9P^2 a^2}{16b^2 E_{11} h^3} \quad (4)$$

where

- P = load
- a = initial crack length
- b = specimen depth
- E_{11} = Young's Modulus
- h = specimen height

Figure 15. Critical Load vs. Crack Length

The critical strain energy release rate was calculated using the expression:

$$G_{IIc} = (P_c^2 / 2B) (dC/da) \quad (5)$$

The value of dC/da was found from the derivative of the compliance curve that was plotted earlier (see Figure 11).

The critical strain energy release rate was calculated for each crack length and compared to the corresponding value obtained from the analytical value of G_{II} (see Table IV).

Table IV. Mode II Fracture Toughness

<u>Crack Length (in)</u>	<u>Critical Load (lbs)</u>	<u>G Experi- mental (lb/in)</u>	<u>G Theore- tical (lb/in)</u>
.1405	268.8	2.165	4.860
.5625	228.1	2.114	7.410
.563	234.4	2.233	7.839

The experimental values of G_{IIC} were within five percent of each other. This was an expected result if the critical strain energy release rate was a material property. Since the values were so consistent, it gives an indication that the test was conducted properly and that the assumptions that were made were correct.

The analytical values of G_{II} , however, not only differed from the experimental results, but also differed greatly from each other. Both the theoretical expressions for compliance and strain energy release rate are based on simple beam theory. For small specimens and small crack lengths simple beam theory is not accurate. Other relationships have to be developed for the small specimen using finite element analysis or another analytical method.

Fracture Surface

After the fracture tests, the fracture surfaces were examined under a microscope at varying powers up to a maximum magnification of 200X. The specimens had already fractured up to the midspan loading point. To view those fracture surfaces, the remaining half of the neutral plane was separated using a Mode I type pulling force. This left a fracture surface that could be divided into four general sections: the notch, the pre-crack, the shear fracture, and the Mode I failure (See Figure 16).

Figure 16. One Fracture Surface
(Top View)

The area of the notch was evident in the photographs (see Figure 17). It showed the effects of the diamond grinding that resulted from the use of the diamond wheel. The notch and the pre-crack show a dramatic change in surface. The pre-crack had a smooth planer surface that continued until it blends into the area of shear failure. There was very little difference between the pre-crack and Mode II fracture. The two ran in the same plane. The surfaces were smooth with relatively few instances of fiber pull out.

The similarity of the pre-crack and failure gave another indication of a good test, since the pre-crack gave the appearance of a natural fracture. The fracture plane was evidence of pure brittle fracture without ductility. The probable failure mechanism was in the fiber-matrix interface or in the matrix itself.

Figure 17. Fracture Surface - Mode II
Diamond ground notch (left), and
Mode II surface (right).

The area of Mode I failure was not as smooth as the first half of the specimen (See Figure 18). The Mode I surfaces exhibited much more destruction to the fibers than was evident in the Mode II failures.

Figure 18. Fracture Surface - Mode I

Magnification 15X

CONCLUSIONS AND RECOMMENDATIONS

The initial objective of this study was to develop a technique that could be used for fracture toughness testing of small composite specimens. The technique was to be developed so that it could be modified for use at elevated temperatures. Finally, this technique was to test some ceramic matrix composite specimens. Based on the completed test, there are several conclusions to be made:

Conclusions

- 1) A test method for finding the critical strain energy release rate, G_{IIC} , for a small ceramic matrix composite specimen was developed.
- 2) The end-notched flexure specimen is a viable specimen for Mode II testing of small composite specimens.
- 3) The LISG provided the instant of crack initiation, which corresponded to the point of nonlinearity on the load-displacement curve.
- 4) G_{IIC} was found for the 1723 glass matrix, silicon carbide fiber composite.
- 5) The analytical expressions for compliance and strain energy release rate need to be modified for use with small composite specimens.

Recommendations

Based on this study, some recommendations of further study can be made.

1) Replace the manual loading device with a finely adjustable, automated loading device. An automated device such as an MTS would allow for much smoother loading rates, loading control and displacement control. It would also allow for cyclic loading, which is needed for fatigue testing. This would alleviate many of the short comings of our present experimental set-up.

2) Improve the existing computer program or write a new program that would allow for more rapid acquisition, more input variables, and varied output. For the rapid failures associated with brittle glasses, data needs to be acquired more than once a second to accurately measure the fracture growth. The present software can only collect data once a second. Also, our technique uses load point displacements versus loads to find specimen compliances. The present computer program was not designed with compliances in mind or G_{II} in mind.

3) Apply this technique to other modes of fracture. Other composite orientations could be used to investigate Mode I or Mixed Mode I and II.

4) One large area of further study would be to apply a variation of this technique to high temperature applications. The LISG and tabbing have been applied to

temperatures up to 1400°C. This work was applied to Mode I failure, however, and could now be expanded to include Mode II fracture. This would involve major changes in material and equipment.

APPENDIX A

The composite used in this study was manufactured at the Air Force Materials Laboratory, Wright Patterson AFB. Larry Zawada (ref. 37), an engineer in the Materials Laboratory provided the direction for the composite fabrication which was based on general concepts worked by Karl Prewo and others (ref. 7-9, 28-36).

Materials

The basic components of the composite are an aluminosilicate glass frit, a binder solution, and the silicon carbide yarn. The glass frit consisted of a 1723 Corning amorphous glass mixture which comes in the form of a finely ground powder. The R Hoplex Binder was in the form of a liquid. The silicon carbide fibers were in the form on a Nicalon yarn manufactured by the Nippon Carbon Company of Tokyo.

The composite was manufactured by the hot pressing of multiple layers of infiltrated unitape. The process of making the unitape begins with the mixing of a liquid slurry. The slurry is composed of a mixture of glass, binder and water. The specific combination used was:

80 grams 1723 Corning Glass Frit

210 milliliters Distilled Water

90 milliliters R Hoplex Binder

Winding

After the slurry has been well mixed, it was used to coat the silicon carbide yarn. The slurry-impregnated yarn was then wound on a mandrel to form unidirectional tapes (see Figure 19).

Figure 19. Winding Process

The winding process was performed manually and each four hour winding produced eight four inch wide plies. The winding was performed by mounting a spool of silicon carbide yarn on a roller at one end of a long work table. A single strand of silicon carbide yarn was gradually pulled through

a hot furnace set a 600 degrees centigrade. As the yarn was pulled through the furnace, a protective coating was burned from the yarn. This left only the silicon carbide material itself. The uncoated yarn was then directed over a set of air jets. The air jets teased the strands of yarn and loosened the bundles of fiber. The loosened yarn was then run through a beaker of the slurry. The slurry was kept constantly agitated by a magnetic spinner located at the bottom of the beaker. The agitation insured a constantly uniform mixture within the slurry and also insured a well impregnated yarn coming out of the slurry. The yarn was then carefully wound on a slowly rotating mandrel. The mandrel was in the form of an octagon with four inch by six inch faces. The slurry impregnated yarn was continuously wound on the mandrel until a four inch wide tape was formed. The tape was formed by multiple parallel windings of yarn with a half diameter overlap on each winding. As the winding progressed, the yarn was gently flattened to ensure that the individual strands of yarn became sufficiently meshed together. A heating lamp was used to slowly dry the newly formed tape on the rotating mandrel. The binder dried to form a rigid tape of fiber and matrix.

Once dry, the unidirectional tape was cut from the mandrel. Each of the eight faces on the mandrel provided a single rough ply approximately four inches by six inches in

size. These rough plies were then cut into smaller plies using a paper cutter. Depending on the final specimen size desired, each rough ply was then cut into four, two by two inch plies or one, four by four inch ply. Each finished ply was visually inspected to insure the quality of the tape. These ply sizes were determined by the molds used in the hot pressing. The specimen thickness was determined by the number of plies stacked together during hot pressing. It took forty plies to achieve our 0.2 inch thick specimen.

Hot Pressing

To make our final unidirectional sample forty plies were stacked in a special graphite die. The inside of the die was lined with tantalum foil to prevent sticking. Molybdenum foil was placed on top of and below the forty plies also to prevent sticking. Finally, graphite plungers were placed in the die and the layers were compacted in a vice.

The graphite die was then placed in a hot press and a thermocouple was inserted into the upper plunges. The hot press was gradually heated to 800 degrees centigrade and the pressure was increased to 500 pounds per square inch. During this time the binder was burned off and any excess gases escaped from the die. The composite was then rapidly heated to a temperature of 1100 degrees centigrade and the pressure

was increased to 1800 pounds per square inch; the composite was held at this final state for ten minutes and then gradually cooled.

The whole process took five hours with constant monitoring by an engineer. The hot press temperature, pressure, and ram displacement were recorded every ten minutes during the run. The engineer looked for trends in the relationships between displacement and temperature based on previous hot pressings of this ceramic composite. This provided one measure of quality control during the fabrication process.

The result of the process was a four by four inch square that was 0.2 inches thick. Surface quality was good and fiber distribution was good (see Figure 20) with about 50 percent volume of fiber. The photograph shown in Figure 19 was taken of a cross section at the center of the four by four inch composite plate. The volume of fiber was calculated from the fiber surface visible in a photomicrograph of the composite.

Appendix B

After the compliance measurements were taken, five specimens were loaded until fracture. The load vs. load point displacement curves are included in the following pages (see Figures 20-24). It was difficult to visually determine the exact point of shear failure; therefore, the load-displacement curves were used to determine the critical load at which the shear fracture propagated.

Each curve exhibits similar trends. Initially, the load-displacement relationship was linear. At a certain point the curves deviated from the initial course and became nonlinear. Finally, the load dropped off.

The point of nonlinearity determined the critical load. It can be seen that the load at the point of nonlinearity decreases with increasing crack length.

Computer Program

The following computer program was written by Jay Jira of the Air Force Materials Laboratory (AFWAL/MLLN), for use with a laser interferometric strain gauge. The program was run on a Tektronix 4052 computer with an auxiliary memory. The program recorded the output voltages from the two photo-multiplier tubes and the load cell. The program allows the user to input information about the specific operating parameters of the equipment and the desired data reading rate. The input voltages were then converted to the appropriate units and were recorded in memory. The computer program processed the load and fringe information into the form of relative displacements. It was then possible to select various plots of load, displacement and time.

VITA

Captain Robert P. Vozzola was born on 7 March 1958 in Hartford, Connecticut. He graduated from high school in Windsor Locks, Connecticut, in 1976 and attended the Worcester Polytechnic Institute of Massachusetts, from which he received the degree of Bachelor of Science in Mechanical Engineering in May 1980. Upon graduation, he received a commission in the USAF through the ROTC program. He was employed as a process engineer, for Reddington Counters, Inc., Windsor, Connecticut, until called to active duty in March 1981. He served as a project engineer and branch chief for the 4501st Computer Services Squadron and the 1912th Information Systems Support Group, Langley, AFB, Virginia until entering the School of Engineering, Air Force Institute of Technology, in May 1986.

UNCLASSIFIED

The need for an accurate fracture toughness testing technique for fiber reinforced ceramic composites was identified. A technique was developed to measure small crack mouth displacements over small gauge lengths of small glass-ceramic composite specimens during loading. The technique was applied to Mode II crack propagation. A loading fixture capable of exerting and measuring small loads was developed. A technique to measure compliances in small composite specimens was perfected. The validity of using a laser based interferometric technique to determine the instant of crack initiation was studied. Finally, the Mode II critical strain energy release rate of interlaminar delamination growth was evaluated. Sample results for a 1723 glass matrix, silicon carbide fiber composite are included and recommendations for further study are described.
